SCHÜTZ A, SKERFVING S, RANSTAM J, CHRISTOFFERSSON J-O. Kinetics of lead in blood after the end of occupational exposure. *Scand J Work Environ Health* 13 (1987) 221–231. The sum of two exponential functions was fitted to the decay of blood lead (PbB) level after the end of lead exposure. For two subjects who had not formerly been occupationally exposed to lead but who had been exposed to a single short heavy dose, the fast compartment (probably soft tissues) had a biological half-time of 27 and 44 d, respectively. For 20 lead workers after the end of occupational exposure, the corresponding median was 29 (range 7–63) d. For 21 ex-lead workers, the median biological half-time of the slow compartment was 5.6 (range 2.3–27) years. There was significant interindividual variation in both the fast and the slow half-time. This finding probably means a considerable variation in risk at a certain exposure level. In the lead workers, the PbB fraction corresponding to the slow compartment had a median as high as 1.8 (range 0.7–2.7) $\mu\text{mol/l}$, which constituted more than half of the total PbB. This fraction was associated with exposure history, and with the lead level in the skeleton, the latter determined in vivo by an X-ray fluorescence method. The data thus indicate a rather rapid turnover of the skeletal lead pool, a phenomenon which may affect the PbB level considerably.

Key terms: half-time, metabolic model, two-compartment model.

Lead exposure is common in industry. The blood lead (PbB) level is the main parameter used for the biological monitoring of lead exposure (74). However, knowledge on the kinetics of PbB is incomplete, as it is regarding the metabolism of lead in the other tissues of the body (74), which is a phenomenon that PbB may mirror.

In the present article we report a study of the decay pattern of lead in the blood of lead-exposed subjects after the end of exposure. This decay pattern could be interpreted by a metabolic model.

Subjects and methods

Subjects and sampling

The first group to be studied was 23 male ex-lead workers (table 1). Their mean age was 55 years and their mean exposure time was 23 years. The PbB was usually determined at the end of exposure and then at varying intervals. For ten subjects PbB was determined once, or more often, a year. For one worker (number 101), no information was available concerning the first year after the end of exposure. For 12 subjects (numbers 104–115), several determinations were made during the first year, then at year seven, and then again from year nine on about twice a year. For one subject (num-

ber 102) there was a lack of data between 3.5 and 9.6 years after the end of exposure.

In addition 17 male lead workers temporarily removed from exposure were investigated (table 2). Their mean age was 49 years, and their mean exposure time was 11 years. The reason for removal from exposure was high PbB levels (generally about 3.0 $\mu\text{mol/l}$ or more). Twelve of the workers were transferred from a smeltery to a nearby plant, the work in which did not involve lead exposure. The PbB level was generally determined when the workers left the smeltery and then once a week for three weeks; later PbB measurements were made once every two to four weeks.

Furthermore, two male volunteers, who had been unexposed occupationally, but who had been exposed to a single short heavy lead dose, were included (table 2). Details on these two subjects have been published elsewhere (56).

Spot determinations of "background" PbB levels were made for 47 healthy workers not occupationally exposed to lead. They lived in the same county as the exposed subjects and were all blue-collar workers. Their average PbB level was 0.3 $\mu\text{mol/l}$. In this connection, it may be mentioned that, for 15 workers in a glue production plant located close to the nonlead resort of the temporarily removed smeltery workers, the average PbB level was 0.5 (range 0.3–0.7) $\mu\text{mol/l}$.

Medical examinations

For most of the subjects, an occupational and medical history, including alcohol habits, was obtained. Venous blood samples were analyzed for lead (see the section Blood Lead Determinations), hemoglobin, sedimentation rate; red and white cell counts; calcium,

phosphate, and creatinine concentrations; and alkaline phosphatase and gamma glutamyl transferase activities in serum. A urine sample was analyzed for albumin and glucose.

Among the ex-lead workers, detailed medical information was lacking for four. Among the 19 remaining, 12 had earlier been removed (at least once) temporarily from lead exposure because of a high PbB level and/or a high delta-aminolevulinic acid level in the urine. One subject was clinically diagnosed as lead poisoned (upper abdominal pain, constipation, neuropathy, and slight anemia) at the time when his exposure ended. No one else had been treated in a hospital because of lead poisoning. One worker had a clinically silent chronic lymphatic leukemia, and one had a type 2 diabetes treated with diet only. Three persons had slight increases in their serum creatinine levels, and two others showed slight albuminuria. Three subjects had somewhat increased gamma glutamyl transferase activities, in their serum, two of whom were known to abuse alcohol.

Among the 17 temporarily removed lead workers, detailed medical information was available for 14. Among these 14, seven had earlier been removed because of a high PbB level and/or a high delta-aminolevulinic acid level in their urine. None had been treated with drugs because of lead poisoning. Three subjects had slightly increased gamma glutamyl transferase activities in their serum, one of whom also had an increased alkaline phosphatase activity in his serum. One person had an isolated marginal increase in alkaline phosphatase activity in his serum.

The two subjects without previous occupational lead exposure were both in excellent health.

Blood lead determinations

Blood was obtained from the cubital vein. During the first years of the study, acid-washed heparinized sampling tubes were prepared at our laboratory. Later on, evacuated, metal-free Vacutainer® tubes were used.

Almost all of the PbB determinations were made in the same laboratory and by the same method. The samples were wet-ashed, and lead was complexed with dithizone, extracted, and determined by flame atomic absorption spectrometry (AAS) (55, 56). The detection limit was 0.05 $\mu\text{mol/l}$ (10 $\mu\text{g/l}$).

Each analytical series contained six samples, two blanks containing reagents only, and four "normal" blood samples (two of them with standard lead addition). All the samples were analyzed twice. The coefficient of variation calculated from duplicate analyses of 25 samples containing 0.5 $\mu\text{mol/l}$ or less was 6.6 % of the mean, for 57 samples containing 0.5–1 $\mu\text{mol/l}$ it was 3.9 %, for 58 samples containing 1–2 $\mu\text{mol/l}$ it was 2.5 %, and for 60 samples containing 2–3.5 $\mu\text{mol/l}$ it was 2.0 %.

The accuracy was tested twice each year in a Nordic interlaboratory calibration program with 6–19 (mean

12) accepted laboratories participating on each occasion. The regression function of our results (Y , $\mu\text{mol/l}$) on the average result of the other laboratories (X) was $Y = 1.008X - 0.052$. Our results for the 115 samples (range 0.2–5.6 $\mu\text{mol/l}$) averaged 96.3 % of the mean (range 80–112 %; 62 % within 95–105 %) of the other laboratories. Furthermore, we participated in the UK External Quality Assessment Scheme during the latter part of the study. In the 29 samples analyzed, our results by single analysis averaged 99 % of the mean (2.40 $\mu\text{mol/l}$) (range 90–115 %; 72 % within 95–105 %) of the about 90 participating laboratories. Neither quality control series displayed any time trend.

During the first year of observation of subjects 104–115, the first three years of subject 102, and the six first years of subject 116, PbB was determined by a colorimetric method after extraction with dithizone in chloroform. The detection limit was about 0.05 $\mu\text{mol/l}$. The results obtained by the colorimetric method averaged 105 (SD 6) % in the concentration range 0.3–1.9 $\mu\text{mol/l}$ and 100 (SD 5) % in the range 2.0–5.4 $\mu\text{mol/l}$ of results obtained with the flame AAS method.

From subject 116, for the following four years, determinations were made by flame AAS after precipitation of proteins with trichloroacetic acid (22). The detection limit was 0.2 $\mu\text{mol/l}$, and the method error about 10 %.

Mathematical analysis

Three models corresponding to the sum of one, two, and three exponentials were considered for the PbB decay curves of each individual worker. A fixed "background" value of 0.3 $\mu\text{mol/l}$ was used for all the subjects and each model. The nonlinear regression procedure in the statistical package BMDP (21) was used. This program produces estimates of the parameters which minimize the unweighted residual sum of squares using a modified Gauss-Newton algorithm. Minimum and maximum values can be specified for each parameter. Thus two parameters and their asymptotic standard deviation were estimated: an elimination rate [transformed and quoted as half-time $T_{1/2}(1)$, $T_{1/2}(2)$, and $T_{1/2}(3)$] and the concentration corresponding to each compartment [$Y(1)$, $Y(2)$, and $Y(3)$]. Confidence intervals were estimated on the assumption of asymptotic normality of the estimates. The fit of the three models was judged from comparison of the fraction of total variance in the PbB values explained (R^2 %). In addition plots of residuals versus time were used for checks of the validity of the model and the accuracy of the individual curve fittings.

To describe accumulation, a function of the type $Y(t) = A\{1 - \exp(-B \times t)\}$, where A is a scale constant, B an elimination constant, and t time, was fitted to the data by use of the nonlinear regression procedure in BMDP (21).

Bone lead levels

Bone lead levels were determined *in vivo* from the middle phalanx of the left forefinger of 37 subjects by an X-ray fluorescence method, as described earlier (16). The detection limit was 20 $\mu\text{g/g}$, and the method error about 15 %. Readings below the detection limit were assigned a value of 10 $\mu\text{g/g}$ in the calculations. In most cases, levels derived either at duplicate measurements (16) or calculated from a series of measurements (15) were employed.

Statistics

In general, nonparametric tests were employed. For associations the Spearman's rank correlation (r_s) was used, and for comparisons of duplicate measurements in the same individual the Wilcoxon's matched-pairs ranked-sign test was used. Comparisons between groups were made by the Mann-Whitney U-test. In a few instances, a single or multiple linear regression analysis was made. For establishing interindividual variations, binomial tests were employed. When more than one observation series was available for a particular individual, the value corresponding to the calculations with the best fit (R^2) of the compartment analysis was used. All P-values are two-tailed. "Statistically significant" denotes $P < 0.05$.

Results

The decline rate of PbB was, in most cases, rapid soon after end of exposure, but later on it was slower (figure 1). There was generally a good fit of the observed PbB to any of the three compartment models tested (tables 1 and 2). However, one subject (number 122) (table 1) displayed pronounced irregularities in the elimination pattern, which rendered serious suspicion of occasional, ongoing exposure. In addition the lack of PbB data during the first 94 d after the stated end of exposure probably contributed to the bad fit to any of the models tested. He has thus been disregarded in the following results. Another ex-lead worker (number 114) was excluded because of suspected lead exposure during the first month of the supposedly exposure-free period (rising PbB). Furthermore, before the second observation period (from year 7 on), his PbB had decreased to very close to the background level, and the $T_{1/2}(2)$ was determined merely from the observations made during the first year. No conclusions as regards the kinetics of a slow compartment seem to be justified in this case.

For most of the ex-lead workers, the number of observations during the first period after the end of exposure was too few (less than four per two months) to allow reasonably accurate estimates of the decay rate of the fast compartment. Thus, for all but three (numbers 102, 103, and 123), an approximate half-time of the fast compartment [$T_{1/2}(1)$] of 30 d was employed. (See the following text.)

The fit of the two-compartment model (median 97 %, range 35–99 %) was considerably and significantly ($P < 0.0001$, Wilcoxon) better than that of the one-compartment model (median 86 %) (tables 1 and 2). The fit of the three-compartment model was similar (medians 97 versus 97 %) (table 1), though significantly ($P < 0.01$, Wilcoxon) better.

When the three-compartment model was employed, the median of $Y(1)$ was 0.6 (range 0.0–2.3) $\mu\text{mol/l}$, that of $Y(2)$ was 1.4 (range 0.0–2.5) $\mu\text{mol/l}$, that of $T_{1/2}(2)$ was 3.7 (range 0.3–16) years, that of $Y(3)$ was 0.3 (range 0.0–2.6) $\mu\text{mol/l}$, and that of $T_{1/2}(3)$ was >100 (range 4.9– ∞) years.

In the following presentation, only the simplest model with a good fit, i.e., the two-compartment one, will be discussed.

With the use of the two-compartment model, the decay rate in the remaining 21 ex-lead workers (table 1) had a median biological half-time of the slow compartment [$T_{1/2}(2)$] of 5.6 years during a median post-exposure period of 13 years. There was a considerable range for $T_{1/2}(2)$, i.e., 2.3–27 years (table 1).

The data were sufficient for an estimate of the half-time of the fast compartment in three of the ex-lead

Figure 1. Decline of the blood lead level (PbB, logarithmic) after the end of exposure for three ex-lead workers. A two-compartment model was fitted to the data. Both compartments and their biological half-times ($T_{1/2}$) are indicated. For subjects 104 and 117, the half-time of the fast compartment [$T_{1/2}(1)$] was assumed to be 30 d. (y = years)

unteers.

^b At the end of exposure.

^c $T_{1/2}(2)$ is assumed to be 5 years.

^d Numbers 201 and 217 are identical to numbers 101 and 117, respectively, in table 1.

^e Two subjects were studied twice. In the statistical calculations, the decay pattern with the best fit was used.

^f Sample obtained 15 d after the end of exposure.

workers (numbers 102, 103, and 123) (table 1) and in the 17 temporarily removed lead workers (table 2). The observation period in the latter group was too short for an accurate estimation of the half-time of the slow compartment [$T_{1/2}(2)$]. Thus, in the calculation of $T_{1/2}(1)$ for these subjects, an approximate $T_{1/2}(2)$ of 5 years (see the preceding text) was used as being the best estimate. The median $T_{1/2}(1)$ for the 20 subjects was 29 d. Their median observation time was 155 d. The range of $T_{1/2}(1)$ was considerable (7–63 d) (table 2) for subjects 203 and 208, the $T_{1/2}(1)$ with the best fit, 49 d and 24 d, respectively, being used. The decay curves with the shortest and next longest $T_{1/2}(1)$, respectively, are shown in figure 2.

When, in two subjects (numbers 203 and 208) (table 2), the decay pattern was studied during two periods of temporary removal from exposure, 0.5 and 1.0 years apart, the decline rates of PbB were compatible.

The two formerly occupationally unexposed subjects had a $T_{1/2}(1)$ of 27 and 44 d (table 2).

The Y intercept of the fast compartment [$Y(1)$] had a median of 0.8 (range 0.0–3.0) $\mu\text{mol/l}$ for the 21 ex-lead workers (table 1), and 1.3 (range 0.5–3.6) $\mu\text{mol/l}$ for the 17 temporarily removed ones (table 2). The difference was statistically significant ($P = 0.007$, Mann-Whitney).

The Y intercept of the slow compartment [$Y(2)$] had a median of 1.8 (range 0.7–2.6) $\mu\text{mol/l}$ for the 21 ex-lead workers (table 1) and a median of 1.8 (range 0.9–2.7) $\mu\text{mol/l}$ for the 17 workers temporarily removed from exposure (table 2). The groups were, of course, not significantly different. For both of the two occupationally unexposed subjects, $Y(2)$ was 0.1 $\mu\text{mol/l}$.

For the 21 ex-lead workers, $Y(2)$ made up for a median of 68 (range 33–100) % of the combined compartments [$Y(1)$ plus $Y(2)$], whereas for the workers

Figure 2. Decline of the blood lead level (PbB, logarithmic) in two lead workers temporarily removed from exposure. A two-compartment model with a biological half-time ($T_{1/2}$) of 5 years for the slow compartment was fitted to the data. Both compartments and their half-times are indicated (From subject 217, the first blood sample was taken 6 d after the end of exposure.) (y = years)

Figure 3. Relationship between the half-time [$T_{1/2}(1)$] and the Y intercept [$Y(1)$] of the fast compartment in a two-compartment model fitted to the decline of the blood lead (PbB) levels after the end of exposure. Closed circles and open squares denote lead workers and volunteers, respectively, in table 2; open circles and triangles denote ex-lead workers in table 1. (Circles = subjects studied up to 5 years, triangles = subjects studied more than 5 years)

Figure 4. Relationship between age and the half-time of the slow compartment [$T_{1/2}(2)$] in a two-compartment model fitted to the decline of blood lead levels after the end of exposure. Symbols as in figure 3. (y = years)

Figure 5. Relationship between time of occupational lead exposure and Y intercept of the slow compartment [Y(2)] in a two-compartment model fitted to the decline of the blood lead (PbB) levels after the end of exposure. Symbols as in figure 3. Subjects 101 and 117 are identical with 201 and 217, respectively. (y = years)

Figure 6. Relationship between the lead level in finger bone (Bone Pb) and the Y intercept of the slow compartment [Y(2)] in a two-compartment model fitted to the decline of blood lead (PbB) after the end of exposure. Symbols as in figure 3. Subjects 101 and 117 are identical with 201 and 217, respectively. Note: The "Y(2)" values are not the same as in tables 1 and 2, as they have been recalculated to the time of the first bone lead determination. The symbols in the shaded area represent bone lead levels below the detection limit (20 μg/g).

temporarily removed from exposure it was 57 (range 27–80) %. The difference was statistically significant ($P = 0.02$, Mann-Whitney). For all the lead workers, the median was 65 %, while the fractions were 6 and 7 % for the two occupationally unexposed subjects.

$T_{1/2}(1)$ correlated significantly with Y(1) ($r_s = 0.41$, $P = 0.03$) (figure 3), but not with age, time of exposure, initial PbB, Y(2), or the serum creatinine levels. For five out of the 20 subjects with an individually estimated $T_{1/2}(1)$, the linear regression line for $T_{1/2}(1)$ upon Y(1) [$T_{1/2}(1) = 5.4 \times Y(1) + 23$] did not run through the 95 % confidence interval of $T_{1/2}(1)$. This result showed that there was a statistically significant ($P = 0.0004$, binomial test) interindividual variation for $T_{1/2}(1)$.

The $T_{1/2}(2)$ of the ex-lead workers correlated significantly with age ($r_s = 0.50$, $P = 0.01$) (figure 4), but not with exposure time, observation time, initial PbB, Y(1), Y(2), or the serum creatinine levels. In 10 out of the 21 subjects, the linear regression line for $T_{1/2}(2)$ upon age [$T_{1/2}(2) = 0.15 \times \text{age} - 1.7$] did not run through the confidence interval of $T_{1/2}(2)$. This finding showed that there was an interindividual variation for $T_{1/2}(2)$ ($P < 0.0001$).

When Y(2), for all 38 lead workers and the two unexposed subjects, was plotted against exposure time (figure 5), there was no significant nonparametric association. Neither was there any linear correlation. However, when an exponential accumulation curve was fitted to the data, there was a reasonable fit ($R^2 = 49$ %, $P < 0.001$). The elimination constant was 1.2, corresponding to a half-time of 0.6 years, and Y(2) leveled off at 1.8 μmol/l.

Moreover, there was a tendency for the workers temporarily removed from exposure to have a higher Y(2) at a particular exposure time than the ex-lead workers. However, the difference was not statistically significant in the multiple regression analysis. Neither did the observation time display any significant association with Y(2).

For the 35 lead workers and the two unexposed subjects, there was a significant correlation between Y(2) and bone lead content ($r_s = 0.36$, $P = 0.01$) (figure 6). Multiple linear regression analysis displayed that there was an increase in Y(2) of 0.008 μmol/l per μg/g of bone-Pb ($P = 0.005$). Furthermore, the temporarily removed workers had a Y(2) that, on the average, was 1.0 μmol/l higher than that of the ex-lead workers. This finding was also obvious from the decrease in Y(2) of 0.09 μmol/l per year of the postexposure observation time ($P < 0.0001$). Among the active workers, there seemed to be a leveling off of Y(2) when the bone lead content increased. There was no such clear corresponding tendency among the retired workers.

Discussion

A multiple exponential model fitted well the decay pattern of PbB. However, there are other possibilities, eg, power functions. Indeed, data indicating a nonlinear

relation between the air lead level and PbB (eg, in references 12, 13, 19), between PbB and plasma lead (20, 42, 45), and between PbB and the lead level in urine (12, 13, 56, 67) could favor the choice of a nonlinear model. However, elimination rates similar to ours have been reported earlier, both for subjects far less (11, 13, 53) and far more (14, 46) exposed. In addition there was no indication in the present data that the elimination rates were faster in subjects with a high initial PbB; instead the $T_{1/2}(1)$ increased with increasing $Y(1)$. Thus there are at present no serious objections against the use of a multiple exponential model, at least not in the PbB concentration range that we have studied.

For a few subjects, the fit was not as good. For five subjects the R^2 was $<80\%$, and for one of them it was 0% . This result may be due to the fact that, in these subjects, the PbB was low during a major part of the observation period and that thus the analytical error had a great impact.

It is relevant to consider whether the number of compartments is two. Different authors have proposed one (23, 68), two (1, 7, 63, 64), three (4, 33, 43, 53, 66), four (13, 23, 44, 45, 60), and even five (6) compartments in human metabolic models. The simplest model that gave a good fit in the present study was the two-compartment one. Thus there was no reason to choose a more-complicated model. Of course, from a theoretical point of view, a larger number of compartments is probable. Thus data from the two subjects exposed only to a single heavy lead dose may indicate an initial very fast decay of PbB (56). For most of the subjects in the present study, such a phenomenon would have remained undetected. There was probably a continuous absorption of lead from the lungs and gastrointestinal tract for some time after the end of exposure. (See the following discussion.) In addition the early observations were few. However, for the two subjects (numbers 208 and 216) from whom frequent observations were made during the first few days after the end of exposure, the data did not indicate any rapid initial decrease. Moreover, in addition to the relatively small number of observations, the limited observation period and the analytical method error may obscure other compartments, especially small or very slow ones. Indeed, some observations in the present study may indicate that the slow compartment really has more than one component. (See the following discussion.)

The parts of the body which constitute the two compartments must also be considered. The only organ containing lead amounts sufficiently large to cover the considerable excretion associated with the decay of the slow compartment [on the order of $0.05\text{--}0.1\text{ mg}/24\text{ h}$ in urine only, for several years (60)] is the skeleton, which contains hundreds of milligrams (1, 15, 16, 39, 59). The identity between the slow compartment and the skeletal pool is also strongly supported by the association between $Y(2)$ and the bone lead content. The soft tissues, including the lung, contain only a few milligrams (10, 59), an amount which fits with the excretion

during the emptying of the fast compartment.

The median half-time of the fast compartment was about one month. There may be errors that affect this estimate. It is difficult to be absolutely sure that the exposure did stop totally at a fixed date; some exposure may have continued after the formal end of exposure. For example, for the temporarily removed smelter workers, the worksite after removal was located only a few hundred meters from the plant. Also, the homes of the workers may have been contaminated. In addition, a worker may have a pool of lead in the lungs and the gastrointestinal tract and thus continue to absorb lead for some time after lead inhalation and ingestion have ceased. The limited data on hand — frequent measurements of two subjects — may indicate such an absorption, but mainly up to one week after the end of exposure, which is in accordance with earlier observations (9, 12, 13, 31, 32). This delayed absorption is probably the reason of the present weak positive correlation between $T_{1/2}(1)$ and $Y(1)$. These possible sources of error all tend to give a somewhat too long an estimate as compared to the true half-time. Furthermore, the workers temporarily removed from exposure were not randomly selected. They were removed from exposure because of high PbB levels, and this occurrence might partly be the result of a slow elimination rate in those particular individuals. Another possible explanation of the slight positive association between $T_{1/2}(1)$ and $Y(1)$ is a bias introduced by the disregarding of possible intermediate compartments.

PbB is mainly present in the red cells. It could thus be suspected that the lifetime of these cells would determine the $T_{1/2}(1)$. However, the calculated $T_{1/2}(1)$ is considerably shorter than would be expected if lead were eliminated from blood only at the normal death of these cells. But lead is known to cause hemolysis, and the question can be raised of whether it could have affected the $T_{1/2}(1)$. Hardly, at least not considerably, as there was no correlation between $T_{1/2}(1)$ and the initial PbB. A negative correlation would be expected if hemolysis were important. For the lead workers temporarily removed from exposure, we had to employ an estimated $T_{1/2}(2)$ of five years. However, this procedure did not affect the $T_{1/2}(1)$; even a $T_{1/2}(2)$ as short as one year, or as long as 10 years, would cause only slight changes in the $T_{1/2}(1)$.

Having taken these possible errors into consideration, we still find it fully justified to conclude that the average $T_{1/2}(1)$ is about one month. This assumption is also compatible with various kinds of earlier data on the elimination (1, 11–14, 20, 27–29, 36, 37, 40, 46, 50, 53, 54, 56, 65), if a second, slow compartment is taken into consideration, and on the accumulation (5, 24, 27, 28, 37, 38, 48, 65, 67) of PbB.

There was a considerable interindividual variation in $T_{1/2}(1)$. To some degree this occurrence may be explained by various errors in the estimates of individual decay curves. Thus the two subjects studied twice had

a different $T_{1/2}(1)$ on the first and second occasion, a finding which could not reasonably be accounted for by real variation. It should be noted though that the half-times were not statistically significantly different, as the confidence intervals overlapped. It is difficult to explain all the variation within the population by errors; there is very probably a true interindividual variation in turnover rate, as has been observed for lead in dogs (23), as well as for other heavy metals in man [methylmercury (58), cadmium (34, 71), chromium (70)], though the true range of the $T_{1/2}(1)$ may perhaps not be as large as 10 times. The interindividual variation may be due to differences in excretion, in urine and/or in feces. However, it was not associated with the serum creatinine levels, and there was no association between elimination rate and urinary lead excretion (60). One possibility is a variation in fecal excretion due to different elimination through bile and/or intestinal reabsorption. In fact, there are indications of a considerable interindividual difference in gastrointestinal absorption (8, 32).

The median half-time of the slow compartment was about five years. Some of the estimates are probably not too accurate because, at lower PbB levels, the analytical method error is more important. In addition, the true "background" PbB may vary somewhat between individuals, even in a population such as the Swedish one, which has low and rather homogeneous PbB levels. Thus a somewhat lower "background" was indicated for subject 104 in the decay curve in figure 1. Furthermore, the number of observations was relatively low, and the observation period should preferably have been a couple of decades. For most of the ex-lead workers, we had to employ an estimated $T_{1/2}(1)$ of 30 d. This procedure may have affected the $T_{1/2}(2)$, but only slightly. However, we consider the median of about five years as reasonably correct. Furthermore, there was definitely an interindividual variation in the $T_{1/2}(2)$. But the true range between individuals cannot be considered firmly established.

There was an increase in the $T_{1/2}(2)$ with increasing age. This phenomenon does not necessarily mean a decrease in the turnover rate of skeletal lead, but may have other explanations. First, senile osteoporosis may add significantly to the mobilization of lead from the skeleton and thus cause a gradual increase in PbB with time, which then leads to a spuriously high $T_{1/2}(2)$. However, for the subjects followed by repeated X-ray fluorescence measurements of bone lead (15, 61), there was no association between age and $T_{1/2}(2)$, and this finding is consistent with the lack of acceleration in the decrease of the bone lead content with time. Second, as lead is excreted by glomerular filtration (69), the decrease of this parameter with increasing age may cause a gradual relative increase in the PbB content, which would result in a spuriously high $T_{1/2}(2)$. We did not see any association between the serum creatinine level and the $T_{1/2}(2)$, but the glomerular filtration rate may decrease considerably without any rise

of serum creatinine. Another possible explanation for the slight association between $T_{1/2}(2)$ and age is that older subjects were exposed to higher lead levels in the past than at present and consequently have a larger pool of "old lead" in a slow pool, from which lead is now returning to the blood. However, the fact that there was no significant association between time of exposure and $T_{1/2}(2)$ speaks against the importance of this phenomenon.

The presence of a lead pool in the body for a long time after the end of exposure has been obvious from a series of investigations (eg, those reported in references 15, 16, 26, 29, 47, 52). The main lead pool is in the skeleton (1, 2, 15, 16, 39, 57, 59). Much has been obscure considering the kinetics of the skeletal lead pool. The $T_{1/2}(2)$ (ie, elimination from the skeleton) of five years reported in the present investigation is faster than most earlier estimates of the half-time of skeletal lead (8–71 years) by different techniques (6, 18, 23, 30, 35, 51, 62, 63, 66). However, it is in accordance with data from some other studies (3, 17, 25, 68, 72, 73). In addition it fits remarkably well the results of repeated X-ray fluorescence measurements of finger bone lead in ex-lead workers [a few of whom are identical with the present subjects (15, 61)]. There are several possible explanations for the differences, ie, the method employed, the part of the skeleton assayed (in our case a reflex of the lead release from the whole skeleton), and the observation time in relation to exposure.

The Y intercepts Y(1) and Y(2) reflect the influence on PbB by the fast and the slow compartment, respectively. The relation between Y(1) and Y(2) varied considerably between different individuals, probably because of the exposure history. Thus, in an individual with a short, heavy exposure, the Y(1) should dominate, while in subjects exposed for many years, though only slightly lately, Y(2) should be more important. It is interesting to note that, overall in the present study, Y(2) made up for as much as 1.8 $\mu\text{mol/l}$, corresponding to 65 % of the PbB concentration, and that it ranged upward as far as 2.7 $\mu\text{mol/l}$ and 100 %. This is a larger fraction than has earlier been assumed (1, 12, 30, 41, 53). The difference may be due to the intensity and time of exposure and the time of observation. The large impact of skeletal lead on PbB is important from a practical point of view, as the fraction of PbB which mirrors the slow compartment decreases only slowly, even after complete removal from exposure.

As has already been mentioned, the slow compartment probably mainly reflects the lead level in the skeleton, which is strongly supported by the association between Y(2) and the lead level in finger bone. The retired workers were lower in Y(2) in relation to finger bone lead than the active ones. In the former, Y(2) may mainly reflect the lead pool in the slow bone lead compartment (53, 63), represented by the mainly cortical (or compact) finger bone; in the latter the fast

trabecular (or cancellous) bone pool may be more important (57). But, in addition, in the active workers, Y(2) may also be affected by a small, intermediately fast pool, perhaps contained mainly in the liver, the kidneys (10, 59), and the skeleton (an even faster pool than the trabecular one). When the data of subject 103 in figure 1 is closely examined, one may, in fact, anticipate more than one component in the slow compartment.

The impact of organs other than the skeleton on Y(2) may be indicated by the accumulation pattern of Y(2) with increasing exposure time. A steady state was reached already within a couple of years. This period is faster than in trabecular bone (57); the turnover of cortical bone is much slower (15, 61). The accumulation pattern may also be affected by the nonlinear behavior of lead in erythrocytes (19, 40, 43). This phenomenon may also be the cause of the apparent leveling off of Y(2) upon lead in finger bone in active workers (but not in the retired ones, who had lower PbB levels).

There was a considerable interindividual variation in Y(2) at a particular exposure time. One obvious explanation is variations in the intensity of exposure. An additional explanation may be the interindividual variations in lead metabolism seen in this study, as well as in earlier ones (8, 32, 60).

The variation in the kinetics of lead metabolism should mean a considerably varying risk for different individuals exposed at the same level, which, of course, is important from a practical point of view. A short $T_{1/2}(1)$, as the result of a rapid excretion, is probably an advantage for the worker. On the contrary, a long $T_{1/2}(2)$ may be good, as it means that the net endogenous exposure from the skeleton is low.

In many countries, lead workers are removed from lead exposure when they reach a PbB "trigger level" ("removal level"; in Sweden at present $3.0 \mu\text{mol/l}$), and they are not allowed to return until the PbB concentration has decreased to a "safe level" ("return level"; $2.0 \mu\text{mol/l}$). In our "typical" lead worker, who had an Y(2) of $1.8 \mu\text{mol/l}$ and a $T_{1/2}(1)$ of one month, this process will take as much as about six months. However, newly employed workers, who have a small Y(2), would display the same decay in less than a month. On the other hand, as many as 57 % (24 of 42) of our workers had a Y(2) of more than $1.7 \mu\text{mol/l}$. On the assumption of a "background" level of $0.3 \mu\text{mol}$, they would reach $2.0 \mu\text{mol/l}$ only after a sufficiently long time had elapsed to affect the slow compartment. In the workers who were followed for a long time, 30 % (7 of 23) would require more than a year to reach the "safe level." These assumptions are in accordance with observations of workers removed from exposure (49).

Acknowledgments

This study was supported by grants 79—72 and 82—160 from the Swedish Work Environment Fund.
